

Chapter 1

Introduction

In particle physics we are concerned about small objects and their interactions. Since the 1970 the dynamics of these tiny pieces are best described by the Standard Model (SM).

The SM contains two groups of fermionic, Spin 1/2 particles. The former group, the Leptons consist of: the electron (e), the muon (μ), the tau (τ) and their corresponding neutrinos ν_e , ν_μ and ν_τ . The latter group, the Quarks contain: u , d (up and down, the so called light quarks), s (strange), c (charm), b (bottom or beauty) and t (top or truth). The SM furthermore differentiates between three fundamental forces (and its carriers): the electromagnetic (γ photon), weak (Z - or W -Boson) and strong (g gluon) interactions. The before mentioned Leptons solely interact through the electromagnetic and the weak force (also referred to as electroweak interaction), whereas the quarks additionally interact through the strong force. A short summary of the taxonomy of the SM can be seen in [fig. 1.1](#)

All of the particles and forces given in the SM are described by a Lagrangian containing 19 parameters. Ten masses, four CKM-matrix parameters, the QCD vacuum angle, the Higgs vacuum expectation value and three gauge coupling constants. Every single parameter has to be fitted from experimental data. Highly accurate values with low errors are crucial for theoretical calculated predictions. One of the major error inputs of every theoretical output are uncertainties in these parameters. In this work we will measure one of these parameters to high precision: the strong coupling α_s , which forms part of the theory of *quantum chromodynamics* (QCD).

As the name suggest¹ the force is characterized by the color charge. Every quark has next to its type one of the three colors blue, red or green. The color force is mediated through eight gluons, which each being bi-colored², interact with quarks and each other. The strength of the strong force is given by the coupling constant α_s . The strong coupling varies with energy and contains an

¹Chromo is the greek word for color.

²Each gluon carries a color and an anti-color.

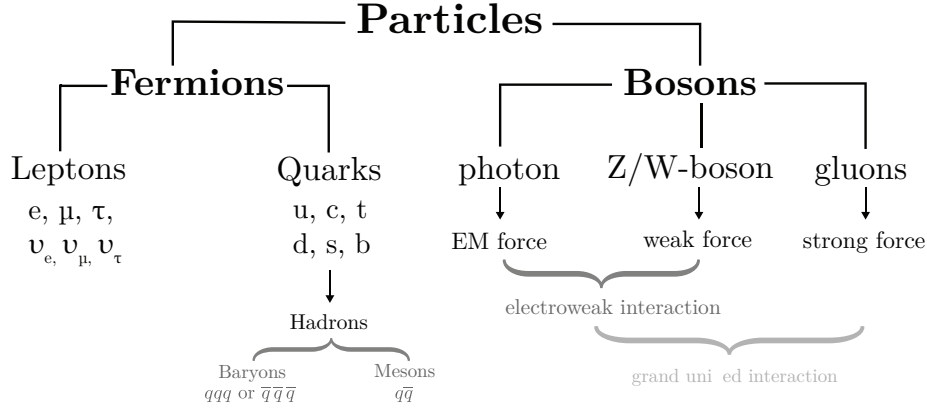

Figure 1.1: Taxonomy of the Standard Model.

exceptional property. It increases with for low energies³. This is exclusive for QCD and has two main implications.

The first implication is that, for low energies the coupling is too strong to isolate quarks. Until now we have not been able to observe an isolated quarks and all experiments can only measure quark compositions. These bound states are called *hadrons* and consist of two or three quarks. *There exist also so-called Exotic hadrons, which have more than three valence quarks.*, which are referred to as Mesons⁴ or Baryons⁵ respectively. This phenomenon, of quarks sticking together as hadrons is referred to as *confinement*. As the fundamental degrees of freedom of QCD are given by quarks and gluons, but the observed particles are hadrons we need to introduce the assumption of *quark-hadron duality*. This means that a physical quantity should be similarly describable in the hadronic picture or quark-gluon picture and that both descriptions are equivalent. As we will see in our work quark-hadron duality is violated for low energies. These so-called *duality violations* have an impact on our strong coupling determinations and can be dealt with either suppression or the inclusion of a model []. Throughout this work will favor and argument for the the former approach.

The second implications concerns *perturbation theory* (PT). The lower the energies we deal with, the higher the value of the strong coupling and the the contributions of *non-perturbative* (NP) effects. Currently there are three solutions to deal with NP effects:

- **Chiral Perturbation Theory** (ChPT): Introduced by Weinberg [Weinberg1978]

³In contrast to the electromagnetic force, where $\alpha(q^2)$ decreases!

⁴Composite of a quark and an anti-quark.

⁵Composite of three quarks or three anti-quarks.

Figure 1.2: Feynman diagrams of the strong interactions with corresponding electromagnetic diagrams. We see that the gluons carry color-charge and thus couple to other gluons, which is not the case for the photons.

in the late seventies ChPT is an effective field theory constructed with a Lagrangian symmetric under chiral transformation in the limit of massless quarks. It's limitations are based in the chiral symmetry, which is only a good approximation for the light quarks u , d and in some cases s .

- **Lattice QCD** (LQCD):
- QCD Sum Rules:

In the following (??) we will describe the τ -decays, which play an essential role in our QCD analysis. Then in [section 1.1](#) we want to give more details of QCD, especially about the coupling constant $\alpha_s(s)$ (which is not constant at all) and the *QCD sum rules*.

1.1 Quantumchromodynamics

QCD gives a complete description of *quarks* and *gluons*. It is born out of the very successful theory of *quantum electrodynamics* (QED), but has some major differences. QED has two well known constituent fields the fermion and the photon. It is also a so called *abelian* theory, meaning that two consecutive rotations commute $AB = BA$. Due to the abelian nature of the QED gauge group $U(1)$ only fermions carry gauge charge. Photons do not carry charge. In contrast QCD takes quarks⁶ and gluons as fields. Additionally QCD is ruled by a *non-abelian* gauge symmetry of $SU(3)$. Thus the group operation of QCD in general do not commute, which leads to gluons carrying charge! This charge is called *color-charge*. The theory requires three colors and describes interactions between a quark of a color with a quark of another color via gluons. Contrary to QED the force carrier, the gluons, interact with themselves, because they carry color charge. The corresponding Feynman diagrams can be seen in [fig. 1.2](#).

⁶Quarks are a subset to the fermions.

Flavour	Mass
u	3.48(24) MeV
d	6.80(29) MeV
s	130.0(18) MeV
c	1.523(18) GeV
b	6.936(57) GeV
t	173.0(40) GeV

Table 1.1: List of Quarks and their masses. The masses of the up, down, strange, charm and bottom quark are the renormalization group invariant (RGI) quark masses and are quoted in the four-flavour theory ($N_f = 2 + 1$) at the scale $\mu = 2 \text{ GeV}$ in the \overline{MS} scheme and are taken from the *Flavour Lattice Averaging Group* [FLAG2019]. The mass of the top quark is not disucess in [FLAG2019] and has been taken from [PDG2018] from direct observations of top events.

The theory of QCD can be summarized with its *Lagrange density* [Jamin2006]:

$$\mathcal{L}_{QCD}(x) = -\frac{1}{4}G_{\mu\nu}^a(x)G^{\mu\nu a}(x) + \sum_A \left[\frac{i}{2}\bar{q}^A(x)\gamma^\mu \overleftrightarrow{D}_\mu q^A(x) - m_A \bar{q}^A(x)q^A(x) \right], \quad (1.1)$$

where $q^A(x)$ represents the quark fields and $G_{\mu\nu}^a$ being the *gluon field strength tensor* given by:

$$G_{\mu\nu}^a(x) \equiv \partial_\mu B_\nu^a(x) - \partial_\nu B_\mu^a(x) + gf^{abc}B_\mu^b(x)B_\nu^c(x), \quad (1.2)$$

where B_μ^a are the *gluon fields*, given in the *adjoint representation* of the $SU(3)$ gauge group with f^{abc} as *structure constants*. Furthermore we have used $A, B, \dots = 0, \dots, 5$ as flavour indices, $a, b, \dots = 0, \dots, 8$ as color indices and $\mu, \nu, \dots = 0, \dots, 3$ as lorentz indices.

1.1.1 Renormalisation Group

The perurbations of the QCD Lagrangian 1.1 lead to divergencies, which have to be *renormalized*. There are different aproaches to 'make' these divergencies finite. The most popular one is **dimensional regularisation**.

In *dimensional regularisation* we expand the four space-time dimensions to arbitrary dimensions. Consequently the in QCD calculations appearing *Feynman integrals* have to be continued to D -dimensions like

$$\mu^{2\epsilon} \int \frac{d^D p}{(2\pi)^D} \frac{1}{[p^2 - m^2 + i0][(q-p)^2 - m^2 + i0]}, \quad (1.3)$$

where we introduced the scale parameter μ to account for the extra dimensions and conserve the mass dimension of the non continued integral.

In addition *physical quantities*⁷ cannot depend on the renormalisation scale μ . Thus the derivative by μ of a general *physical quantity* $R(q, a_s, m)$ that

⁷Observables that can be measured.

depends on the external momentum q , the renormalised coupling $a_s \equiv \alpha_s/\pi$ and the renormalized quark mass m has to yield zero

$$\mu \frac{d}{d\mu} R(q, a_s, m) = \left[\mu \frac{\partial}{\partial \mu} + \mu \frac{da_s}{d\mu} \frac{\partial}{\partial m} + \mu \frac{dm}{d\mu} \frac{\partial}{\partial m} \right] R(q, a_s, m) = 0. \quad (1.4)$$

eq. (1.4) is referred to as **renormalization group equation** and is the basis for defining the *renormalisation group functions*:

$$\beta(a_s) \equiv -\mu \frac{da_s}{d\mu} = \beta_1 a_s^2 + \beta_2 a_s^3 + \dots \quad \beta - \text{function} \quad (1.5)$$

$$\gamma(a_s) \equiv -\frac{\mu}{m} \frac{dm}{d\mu} = \gamma_1 a_s + \gamma_2 a_s^2 + \dots \quad \text{anomalous mass dimension.} \quad (1.6)$$

Running gauge coupling

The β -function and the anomalous mass dimension are responsible for the running of the strong coupling and the running of the quark mass respectively. In this section we will shortly review the β -function and its implications on the strong coupling, whereas in the following section we will discuss the anomalous-mass dimension.

Regarding the β -function we notice, that $a_s(\mu)$ is not a constant, but *runs* by varying its scale μ . Lets observe the running of the strong coupling constant by integrating the β -function

$$\int_{a_s(\mu_1)}^{a_s(\mu_2)} \frac{da_s}{\beta(a_s)} = - \int_{\mu_1}^{\mu_2} \frac{d\mu}{\mu} = \log \frac{\mu_1}{\mu_2}. \quad (1.7)$$

To analytically evaluate the above integral we can approximate the β -function to first order, with the known coefficient

$$\beta_1 = \frac{1}{6}(11N_c - 2N_f), \quad (1.8)$$

yielding

$$a_s(\mu_2) = \frac{a_s(\mu_1)}{\left(1 - a_s(\mu_1)\beta_1 \log \frac{\mu_1}{\mu_2}\right)}. \quad (1.9)$$

As we have three colours $N_c = 3$ and six flavours $N_f = 6$ the first β -function 1.5 is positive. Thus for $\mu_2 > \mu_1$ $a_s(\mu_2)$ decreases logarithmically and vanishes for $\mu_2 \rightarrow \infty$. This behaviour is known as *asymptotic freedom*. The coefficients of the β -function are currently known up to the 5th order and listed in the appendix ??.

As QCD we have three colors and six flavours the beta function carries a negative sign (see eq. (1.8)). This implies that the strength of the coupling is **decreasing** for increasing energies. In QED we have a beta-function with a positive sign and thus its coupling strength increases with energy. This behaviour of QCD leads to *confinement* and *asymptotic freedom*.

Color confinement, or simply confinement, means that color charged quarks cannot be isolated. They always appear in composite hadrons. Until today

no quark has been measured as single particle. There is no analytic proof of confinement, but until today no single quark has been observed. It is qualitatively explained with the gluon field carrying color charge. These gluons form so-called *flux-tubes* between quarks, which cause a constant strong force between particles regardless of their separation. Consequently the energy needed to separate quarks is proportional to the distance between them and at some point there is enough energy to favour the creation of a new quark pair. Thus before separating two quarks we create a two new quarks and we will probably never be able to observe an isolated quark.

For high energies, or very close quarks, the QCD coupling becomes weak and the quarks and gluons are essentially free. This phenomenon is referred to as asymptotic freedom.

Running quark mass

Not only the coupling but also the masses carry an energy dependencies, which is governed by the *anomalous mass dimension* $\gamma(a_s)$.

The properties of the running quark mass can be derived similar to the gauge coupling. Starting from integrating the *anomalous mass dimension* 1.6

$$\log \frac{m(\mu_2)}{m(\mu_1)} = \int_{a_s(\mu_1)}^{a_s(\mu_2)} da_s \frac{\gamma(a_s)}{\beta(a_s)} \quad (1.10)$$

we can approximate the *anomalous mass dimension* to first order and solve the integral analytically [Schwab2002]

$$m(\mu_2) = m(\mu_1) \left(\frac{a(\mu_2)}{a(\mu_1)} \right)^{\frac{\gamma_1}{\beta_1}} (1 + \mathcal{O}(\beta_2, \gamma_2)) . \quad (1.11)$$

As β_1 and γ_1 (see ??) are positive the quark mass decreases with increasing μ . The general relation between different scales is given by

$$m(\mu_2) = m(\mu_1) \exp \left(\int_{a_s(\mu_1)}^{a_s(\mu_2)} da_s \frac{\gamma(a_s)}{\beta(a_s)} \right) \quad (1.12)$$

and can be solved numerically to run the quark mass to the needed scale μ_2 .

QCD in general has a precision problem caused by uncertainties and largeness of the strong coupling constant α_s . The fine-structure constant (the coupling constant of QED) is known to eleven digits, whereas the strong coupling is only known to about four. Furthermore for low energies the strong coupling constant is much larger than the fine-structure constant. E.g. at the Z -mass, the standard mass to compare the strong coupling, we have an α_s of 0.11, whereas the fine structure constant would be around 0.007. Consequently to use PT we have to calculate our results to much higher orders, including tens of thousands of Feynman diagrams, in QCD to achieve a precision equal to QED. For even lower energies, around 1 GeV, the strong coupling reaches a critical value of ≈ 0.5 leading to a break down of PT.

In this work we try to achieve a higher precision in the value of α_s . Our method to measure the strong coupling is called **QCD sum rules**, which by itself is based on a concept called the *two-point function* for which we will devote the following section.

1.1.2 Two-Point function

The vacuum expectation value of the product of the conserved noether current $J_\mu(x)$ at different space-times points x and y is known as the **two-point function** (or simply **correlator**)

$$\Pi_{\mu\nu}(q^2) = \langle 0 | J_\mu(x) J_\nu(y) | 0 \rangle, \quad (1.13)$$

where the noether current is given by

$$J_\mu(x) = \bar{q}(x) \Gamma q(y) \quad (1.14)$$

, where Γ stands for one of the dirac matrices $\Gamma \in \{1, i\gamma_5, \gamma_\mu, \gamma_\mu \gamma_5\}$, specifying the quantum number of the current (S: *scalar*, P: *pseudo-Scalar*, V: *vectorial*, A: *axial-vectorial*, respectively).

The correlator tensor $\Pi_{\mu\nu}(q^2)$ can be lorentz decomposed to a scalar function $\Pi(q^2)$. There are only two possible terms that can reproduce the second order tensor $q_\mu q_\nu$ and $q^2 g_{\mu\nu}$. The sum of both multiplied with two arbitrary functions $A(q^2)$ and $B(q^2)$ yields

$$\Pi_{\mu\nu}(q^2) = q_\mu q_\nu A(q^2) + q^2 g_{\mu\nu} B(q^2). \quad (1.15)$$

By making use of the **Ward-identity** [Peskin1995]

$$q^\mu \Pi_{\mu\nu}(q^2) = q^\nu \Pi_{\mu\nu} = 0 \quad (1.16)$$

we can demonstrate, that the two arbitrary functions are related

$$\begin{aligned} q^\mu q^\nu \Pi_{\mu\nu} &= q^4 A(q^2) + q^4 B(q^2) = 0 \\ \implies A(q^2) &= -B(q^2). \end{aligned} \quad (1.17)$$

Thus redefining $A(q^2) \equiv \Pi(q^2)$ we expressed the correlator as a scalar function

$$\Pi_{\mu\nu}(q^2) = (q_\mu q_\nu - q^2 g_{\mu\nu}) \Pi(q^2). \quad (1.18)$$

The scalar QCD two point function can then be related to the spectrum of hadronic states. The correlator is then related to an integral over the **spectral function** $\rho(s)$ via the *Källén-Lehmann spectral representation* [Kallen1952, Lehmann1954], which is known since the early fities

$$\Pi(q^2) = \int_0^\infty ds \frac{\rho(s)}{s - q^2 - i\epsilon}. \quad (1.19)$$

Equation 1.19 is referred to as **dispersion relation** analogous to similar relations which arise for example in electrodynamics and defines the **spectral function** (a derivation can be found in [Rafael1997])

$$\rho(s) = \frac{1}{\pi} \text{Im} \Pi(s). \quad (1.20)$$

Until now we connected theoretical correlators with the measurable hadronic spectrum. Nevertheless the analytic properties of the correlators have to be discussed as the function has discontinuities.

The main contribution from the spectral function given in eq. (1.19) are the hadronic final states

$$2\pi\rho(m^2) = \sum_n \langle 0 | J_\mu(x) | n \rangle \langle n | J_\nu(y) \rangle (2\pi^2)^4 \delta^{(4)}(p - p_n), \quad (1.21)$$

which lead to a series of continuous poles on the positive real axis for the two-point function, see Fig. 1.3. These discontinuities can be tackled with *Cauchy's*

Figure 1.3: Analytic structure in the complex q^2 -plane of the Fourier transform of the two-point function. The hadronic final states are responsible for poles appearing on the real-axis. The one-particle states contribute as isolated pole and the multi-particle states contribute as bound-states poles or a continuous “discontinuity cut” [Peskin1995].

theorem, which we will apply in ??.

Until now we exclusively dealt with the perturbative (PT) part of the theory, but QCD is known to have not negligible non-perturbative (NPT) contributions. Thus before continuing with the *Sum Rules* we need a final ingredient the operator product expansion, which implements NPT contributions to our theory.

1.1.3 Operator Product Expansion

The **Operator Product Expansion** (OPE) was introduced by Wilson in 1969 [Wilson1969]. The expansion states that non-local operators can be rewritten into a sum of composite local operators and their corresponding coefficients:

$$\lim_{x \rightarrow y} \mathcal{O}_1(x) \mathcal{O}_2(y) = \sum_n C_n(x-y) \mathcal{O}_n(x), \quad (1.22)$$

where $C_n(x-y)$ are the so-called *Wilson-coefficients*.

The OPE lets us separate *short-distance* from *long-distance* effects. In perturbation theory (PT) we can only amount for *short-distances*, which are equal to high energies, where the strong-coupling α_s is small. Consequently the OPE decodes the long-distance effects in the higher dimensional operators.

The form of the composite operators are dictated by Gauge- and Lorentz symmetry. Thus we can only make use of operators of even dimension. The operators up to dimension six are given by [Pascual1984]

$$\begin{aligned} \text{Dimension 0: } & \not{1} \\ \text{Dimension 4: } & : m_i \bar{q} q : \\ & : G_a^{\mu\nu}(x) G_{\mu\nu}^a(x) : \\ \text{Dimension 6: } & : \bar{q} \Gamma q \bar{q} \Gamma q : \\ & : \bar{q} \Gamma \frac{\lambda_a}{2} q_\beta(x) \bar{q} \Gamma \frac{\lambda_a}{2} q : \\ & : m_i \bar{q} \frac{\lambda_a}{2} \sigma_{\mu\nu} q G_a^{\mu\nu} : \\ & : f_{abc} G_a^{\mu\nu} G_b^{\nu\delta} G_c^{\delta\mu} :, \end{aligned} \quad (1.23)$$

where Γ stands for one of the dirac matrices $\Gamma \in \{1, i\gamma_5, \gamma^\mu, \gamma^\mu \gamma_5\}$, specifying the quantum number of the current (S, P, A, respectively). As all the operators appear normal ordered they vanish by definition in PT. Consequently they appear as **Condensates** in Non-perturbative (NPT) QCD like quark-condensate $\langle \bar{q} q \rangle$ or the gluon-condensate $\langle a G G \rangle$ (both of dimension four). These non-vanishing condensats characterize the QCD-vacuum.

As we work with dimensionless functions (e.g. Π) in Sum Rules, the r.h.s. of ?? has to be dimensionless. Consequently the Wilson-coefficients have to cancel the dimension of the operator with their inverse mass dimension. To account for the dimensions we can make the inverse momenta explicit

$$\Pi_{V/A}^{OPE}(s) = \sum_{D=0,2,4,\dots} \frac{c^{(D)} \langle \mathcal{O}^{(D)}(x) \rangle}{-s^{D/2}}, \quad (1.24)$$

where we used $C^{(D)} = c/(-s)^{D/2}$ with D being the dimension. Consequently the OPE should converge with increasing dimension for sufficiently large momenta s .

Let's show how the OPE contributions are calculated with a the “standard example” (following [Pascual1986]), where we compute the perturbative and quark-condensate Wilson-coefficients for the ρ -meson. For the ρ -meson, which is composed of u and d quarks, the current of eq. (1.13) takes the following form

$$j^\mu(x) = \frac{1}{2} \left(: [\bar{u} \gamma^\mu u](x) - \bar{d} \gamma^\mu d(x) \right). \quad (1.25)$$

Figure 1.4: Feynman diagrams of the perturbative (a) and the quark-condensate (b) contribution. The upper part of the right diagram is not wick-contracted and responsible for the condensate.

In fig. 1.4 we draw the Feynman-diagram, from which we can take the uncontracted mathematical expression for the scalar correlator

$$\begin{aligned} \Pi(q^2) = & -\frac{i}{4q^2(D-1)} \int d^D x e^{iqx} \langle \Omega | T \{ : \bar{u}(x) \gamma^\mu u(x) - \bar{d}(x) \gamma^{\mu u} d(x) : \\ & \times : \bar{u}(0) \gamma_\mu u(0) - \bar{d}(0) \gamma_\mu d(0) : \} \rangle. \end{aligned} \quad (1.26)$$

Using Wick's theorem we can contract all of the fields and calculate the first term of the OPE (\mathcal{K}), which represents the perturbative contribution of the OPE (\mathcal{K})

$$\begin{aligned} \Pi(q^2) = & \frac{i}{4q^2(D-1)} (\gamma^\mu)_{ij} (\gamma_\mu)_{kl} \int d^D x e^{iqx} \\ & \times \left[\overline{u_{j\alpha}(x) \bar{u}_{k\beta}(0)} \cdot \overline{u_{l\beta}(0) \bar{u}_{i\alpha}(x)} + (u \rightarrow d) \right] \\ & = \frac{3}{8\pi^2} \left[\frac{5}{3} - \log \left(-\frac{q^2}{\nu^2} \right) \right]. \end{aligned} \quad (1.27)$$

To calculate the higher dimensional contributions of the OPE we use the same techniques as before, but leave some of the fields uncontracted. For the quark-condensate, which we want to derive for tree-level, we leave two fields uncontracted

$$\begin{aligned} \Pi(q^2) = & \frac{i}{4q^2(D-1)} (\gamma^\mu)_{ij} (\gamma_\mu)_{kl} \int d^D x e^{iqx} \left[\right. \\ & + \overline{u_{j\alpha}(x) \bar{u}_{k\beta}(0)} \cdot \langle \Omega | : \bar{u}_{i\alpha}(x) u_{l\beta}(0) : | \Omega \rangle \\ & \left. + \overline{u_{l\beta}(0) \bar{u}_{i\alpha}(x)} \cdot \langle \Omega | : \bar{u}_{k\beta}(0) u_{j\alpha}(x) : | \Omega \rangle + (u \rightarrow d) \right]. \end{aligned} \quad (1.28)$$

The non contracted fields can then be expanded in x

$$\begin{aligned} \langle \Omega | : \bar{q}(x) q(0) : | \Omega \rangle = & \langle \Omega | : \bar{q}(0) q(0) : | \Omega \rangle \\ & + \langle \Omega | : [\partial_\mu \bar{q}(0)] q(0) : | \Omega \rangle x^\mu + \dots \end{aligned} \quad (1.29)$$

and redefined to a more elegant notation

$$\langle \bar{q} q \rangle \equiv \langle \Omega | : \bar{q}(0) q(0) : | \Omega \rangle. \quad (1.30)$$

The finally result can be taken from [Pascual1984] and yields

$$\Pi_{(\rho)}(q^2) = \frac{1}{2} \frac{1}{(-q^2)^2} \left[m_u \langle \bar{u} u \rangle + m_d \langle \bar{d} d \rangle \right]. \quad (1.31)$$

The usage of the OPE and its validity is far from obvious. We are deriving the OPE from matching the Wilson-coefficients to Feynman-graph analyses. These Feynman-graphs are calculated perturbatively but the coefficients with dimension $D > 0$ correspond to NPT condensates!

Having gathered all of the necessary concepts we can close the gap between the theory and experiment in the last section of the introduction: QCD Sum Rules.

1.1.4 Sum Rules

To relate the measurable hadronic final states of a QCD process (e.g. τ -decays into Hadrons) to a theoretical calculable **QCD sum rules** have been employed by Shifman in the late sevent [Shifman1978].

The sum rules are a combination of the two-point function and its analyticity, the OPE, a dispersion relation, the optical theorem and quark hadron duality.

The previously introduced two-point function eq. (1.13) is generally described by the OPE to account for NPT effects.

$$\Pi(q^2) = \Pi^{OPE}(q^2). \quad (1.32)$$

Furthermore it is related to the theoretical spectral function $\rho(s)$ via a dispersion relation (eq:dispersionRelation). Using QCD we are computing interactions based on quarks and gluons, but due to confinement, we are only able to observe Hadrons. Consequently to connect the theory to the experiment we have to assume **quark-hadron duality**⁸, which implies that physical quantities can be described equally good in the hadronic or in the quark-gluon picture. Thus we can rewrite the dispersion relation eq. (1.19) as

$$\Pi_{th}^{OPE}(q^2) = \int_0^\infty \frac{\rho_{exp}(q^2)}{(s - q^2 - i\epsilon)}, \quad (1.33)$$

where we connected the theoretical correlator Π_{th} with the experimental measurable spectral function ρ_{exp} .

We have seen that the theoretical description of the correlator Π_{th} contains poles on the real axis, but the experimental data ρ_{exp} is solely accesible on the positive real axis. Thus we have to make use of Cauchy's theorem to access the

⁸Or simply duality.

theoretical values of the two-point function close to the positive real axis (see [section 1.1.4](#)) given by

$$\int_{\mathcal{C}} f(z) dz = 0, \quad (1.34)$$

where $f(z)$ is an analytic function on a closed contour \mathcal{C} .

Figure 1.5: Analytical structure of $\Pi(s)$ with the used contour \mathcal{C} for the final QCD Sum Rule expression [eq. \(1.35\)](#).

The final ingredient of the QCD sum rules is the *optical theorem*, relating experimental data with the imaginary part of the correlator (the spectral function $\rho(s)$).

In total, with the help Cauchy's theorem, the QCD sum rules can be summed up in the following expression

$$\frac{1}{\pi} \int_0^\infty \frac{\rho_{exp}(t)}{t-s} dt = \frac{1}{\pi} \oint_{\mathcal{C}} \frac{\text{Im } \Pi_{OPE}(t)}{t-s} dt, \quad (1.35)$$

where the l.h.s. is given by the experiment and the r.h.s. can be theoretically evaluated with by applying the OPE of the correlator $\Pi_{OPE}(s)$.
